Dear Readers,

For many years we have faced a decline in funding for agricultural research and extension. Food scarcity and the high food prices highlight the need to reverse this trend and reinvest in both science and its delivery. While gaps in agricultural science between countries do exist, for many millions of farmers in developing countries the lack of professional advice seriously impairs their ability to produce efficiently. Farmers need advice! Now is the time to re-invest in extension in developing countries, and our role at IPI is to increase our contribution in this important area.

Fertilizer use in Africa is extremely low. Consequently, so are yields. IPI, in collaboration with the International Fertilizer Development Center (IFDC), the International Fertilizer Association (IFA), and the International Plant Nutrition Institute (IPNI), has recently launched a project in the Beira Corridor of Mozambique, with the aim of intensifying maize production in the region. Our vision is to enable farmers and the related input and output markets in this region, to realize the benefits maize can provide. This is the first project for IPI in sub-Saharan Africa – and we are very proud to be part of it. We will report on project progress in a future issue of e-ifc.

In this issue of e-ifc, you will find a report from Central Europe on results from long-term field experiments, describing yields and potassium status in soil. The results from 33 sites in six countries demonstrate that omission of K fertilizer has severe consequences. Lessons from such experiments are essential in assessing the sustainability of agricultural production systems in other regions. You can also review research work conducted in India on the effect of potassium on reduction of Cd uptake and oxidative burst in mustard plants. And, under the title “Potassium improves grain filling – a short story in pictures and figures from India, Indonesia and China” we present data describing this phenomena. We hope that this valuable information will be of assistance to field and extension workers in identifying the correct crop responses to K fertilizers.

I wish you all an enjoyable read.

I Long-term field experiments in Central Europe

Dr. Thomas Popp, IPI Coordinator Central Europe

Introduction

Long-term field experiments (LTFE) have a long tradition in the countries of Central Europe, the oldest trial in Skierniewice, Poland beginning in 1923. Many other trials were established in the late sixties and early seventies and have been in operation for almost 40 years (Table 1). The exciting part of these trial projects is that the experiments have been set up on very different soil types varying in soil texture and are being carried out under different climatic conditions, with annual precipitation from 425 to 798 mm and an average temperature from 6.5 °C to 12.0 °C.

A very extensive programme of LTFE is established in the Czech Republic with 15 trials (Fig. 1), of which nine trials are set up in the potato growing area and six in the more favourable sugar beet growing area (Table 2). All the trials are supervised by ÚKZÚZ, the Central Institute for Supervising and Testing in Agriculture.

Quite a large programme also exists in Hungary, which started as a national project in 1967 (Table 1). The LTFE comprises nine trial sites, and with two different crop rotations and one maize monoculture 20 NP and NPK treatments with various application rates being covered. Different institutions are managing the various trial sites; unfortunately because of financial problems the results from the trial sites have not been summarized over the past two years.

Following the same tradition as in the Czech Republic, ÚKSÚP is handling the trial programme in Slovakia. The structure is similar to that of the Czech Republic, the only difference being that in Slovakia, three growing areas are distinguished, which includes that of maize as well as potato and sugar beet (Table 2).

The oldest LTFE in Skierniewice, Poland (started in 1923) can perhaps be mentioned in the same breath as Rothamsted, UK (1843) and Bad Lauchstädt, Germany (1902). In fact for the Polish LTFE we can talk about three different field research projects, an arbitrary rotation with and without legumes, a crop rotation with five crops (Table 3), and potato and rye monoculture. This year the 85th anniversary was celebrated, and this event honoured by holding an international conference about potassium and magnesium which took place at the beginning of June 2008. A second LTFE in Poland is located in the northern part of the country near the town of Ostroda.

Eight different N:P:K-ratios are compared with and without application of farmyard manure.

We are aware of one LTFE in Bulgaria and 11 trials in Romania, but we have experimental findings from only one site. This is in Livada, where two trials are located. The first deals with nine different application rates of lime in

Research findings

combination with eight nutrient treatments and started in 1961, the second has 5 P x 5 N rates, 4 NP x 4 K rates and 4 NP rates x 4 farmyard manure rates and was first carried out in 1967. The LTFE in Plovdiv, Bulgaria was established in 1959 and has 7 treatments with different NPK application rates (N₃₅P₆₀K₉₀, N₅₀₀P₃₀₀K₂₀₀, N₅₀₀P₃₀₀K₀). One trial follows a normal crop rotation (Table 4), the other trial has alfalfa as a monoculture.

Results from LTFE

Czech Republic

Almost four full cycles of crop rotations, each comprising eight different crops (one crop per year), have been evaluated over a period from 1972 till 2002. As the different fertilizer treatments did not show a significant effect on yield in the more fertile sugar beet growing area, this data is not shown here. Nevertheless, increasing potassium application rates had an enormous influence on yield development on the more marginal soils of the potato growing area (Fig. 2). The results show that N, P and K contributed approximately to an additional 50 per cent yield over the years. Between K₀ and K₁₅₈ with constant application of 88 and 80 kg N and P₂O₅, respectively, 108 kg K₂O/ha K contributed an additional 10 per cent of yield.

When K application was neglected over a period of 22 years, the K balance was negative at 87.7 kg K₂O/ha (Fig. 3). Soil K content dropped from 168 mg/kg soil

Research findings

at the beginning of the field trial to 132 mg/kg soil during 1981 – 1983 and further to 107 mg/kg soil during 2000 – 2002. Only with an annual application rate of 158 kg K₂O/ha could a positive K balance be achieved and available K in the soil be maintained at almost the same level. This data shows that soil K fertility is maintained only with constant application of potassium.

Hungary

The results from four sites (Bicsérd, Iregszemcsé, Keszthely, Mosonmagyaróvár) were evaluated for grain maize which was cultivated seven times during the period 1989 till 2001. If we sum up the accumulated yield differences as of the untreated control plot in 1989 we see that omission of all nutrients created a yield loss of 5.57 mt/ha (Fig. 4). If N only was applied, a certain yield increase could be recognised, which resulted in a cumulative yield of 10.18 mt/ha until 2001. The additional application of phosphate did not show much effect during the first years until 1997, but during the last two years the NP treatment gave a 21.7 per cent yield increase as compared to N only. However, balanced fertilization with the addition of 200 kg K₂O/ha resulted in an accumulated yield increase of 13.22 mt/ha (Fig. 4).

Results of soil K (Table 5) in the four sites show that in two of the sites (Iregszemcsé and Keszthely), soil K was decreased during the period 1987-1999 when K was not applied (control plots), but in all four sites soil K was either maintained or even increased when K was applied at 200 kg K₂O/ha.

Research findings

Poland

The LTFE in Skierniewice has produced thousands of results during its duration giving rise to numerous publications. As an example we present some data, which was published by S. Mercik and W. Stepień in Fragmenta Agronomica 2005. These demonstrate the effect of the different nutrient combinations and three cultivation systems on yield of rye, a crop which is extensively grown in Poland. The results clearly show that only with a sustainable fertilizer application of all important nutrients, could the highest yield be achieved (Fig. 5). Monoculture of rye leads to a significant reduction of yield, especially when the application of nutrients was limited. A similar trend but on a higher level can be demonstrated, if the application of farmyard manure and the incorporation of legume crops in the rotation are neglected. The lack of nitrogen was the most important factor limiting yields (-31% to -52%), followed by phosphorus (-17% to -34%) and potassium (-10% to – 18%).

In conclusion, the 33 LTFE experiments described in Central Europe are well able to demonstrate the various benefits that can be learned only over a relatively long time span of 40 years of repeated cropping systems. These experiments show that with adequate supply of nutrients, that both high yields as well as soil fertility can be maintained as indicated by K balance calculations and soil K levels. The effects of insufficient supply of potassium are hard to detect over an annual cycle, and only LTFE can demonstrate the slow, costly reduction in productivity of crops.

Fig 5. The effect of N, P and K omission as compared to control (full omission) and full NPK application on yields of rye in Skierniewice, Poland (average of six crops, 1976-2004).

Note: N, P₂O₅ and K₂O are 90, 30 and 110 kg/ha, respectively. Lime application was given at 2.0 mt/ha every five years for the rotation with FYM and legumes, and at 1.6 mt/ha every four years to the No FYM or legumes, and Monoculture (rye only) rotations.
**Research findings**

**II Potassium nutrition reduces cadmium accumulation and oxidative burst in mustard (Brassica campestris L.)**

By S. Umar(1), I. Diva, N.A. Anjum(2), and M. Iqbal, Department of Botany, Jamia Hamdard, New Delhi - 110062.

**Abstract**

A greenhouse pot experiment was conducted to study the protective effect of potassium (K) nutrition against cadmium (Cd) toxicity in mustard (Brassica campestris L.). Cadmium treatment drastically reduced plant growth (plant dry mass, leaf area), photosynthetic traits (net photosynthetic rate, stomatal conductance and internal CO₂ concentration) and the contents of ascorbic acid (AsA), glutathione (GSH) and potassium (K) but significantly increased the contents of thiobarbituric acid reactive substances (TBARS), hydrogen peroxide (H₂O₂) and Cd ions in the leaves. K application was effective in decreasing the Cd-toxicity-induced oxidative burst as evident from the lowering of H₂O₂ and TBARS, increase of AsA and GSH contents as well as enhanced plant growth. These effects of K were associated with a sharp decline in Cd content of leaves. The results are indicative of the ameliorative role of K in mustard against the oxidative stress caused by Cd toxicity.

**Key words**: Brassica campestris; Cadmium toxicity; Oxidative damage; Potassium nutrition.

**Abbreviations**: APX, ascorbate peroxidase; AsA, ascorbic acid; CAT, catalase; Cd, cadmium; DAS, days after sowing; GR, glutathione reductase; gs, stomatal conductance; GSH, glutathione reduced; Ci, intercellular CO₂ concentration; PN, net photosynthetic rate; ROS, reactive oxygen species; SOD, superoxide dismutase; TBARS, thiobarbituric acid reactive substance.

**Introduction**

Cadmium (Cd), a toxic element, is dispersed in the natural and agricultural environments mainly through human activities and has a long biological half-life (Wagner 1993). It is one of the non-essential heavy metals, toxic to flora and fauna, which is easily taken up by plant roots and translocated to the aerial plant parts (Zhao et al. 2003; Yang et al. 1998). Cadmium accumulation reduces photosynthesis, disturbs plant-water relations and the uptake and translocation of nutrients, and results in visible injury symptoms and/or plant death (Drazkiewicz et al. 2003; Hsu and Kao 2007; Anjum et al. 2008a). Cadmium is known to cause a burst of reactive oxygen species (ROS) in plant tissues, leading to the development of secondary oxidative stress (Qadir et al. 2004; Anjum et al. 2008b, c) that may damage photosynthetic pigments and other bio-molecules such as lipids, proteins and nucleic acids. It causes leakage of electrolytes via lipid peroxidation, a decrease in the AsA and GSH contents and alteration in activities of antioxidant enzymes such as superoxide dismutase (SOD, EC 1.15.1.1), catalase (CAT, EC 1.11.1.6), ascorbate peroxidase (APX, EC 1.11.1.11) and glutathione reductase (GR, EC 1.6.4.2) (Kuo and Kao 2004; Chaoui et al., 1997; Dixit et al. 2001; Chien et al. 2002; Mobin and Khan 2007; Anjum et al. 2008a, b, c, d). The mineral-nutrient status of plants has a regulatory role with reference to plant resistance to stress factors (Marschner 1995). Potassium (K) is an important macronutrient and the most abundant

---

Research findings

cation in plant tissues (Zhao et al. 2003; Jordan-Meille and Pellerin 2007). Increasing evidence suggests that raising K-nutrition status of plants can dramatically inhibit the generation of ROS by reducing the activity of NAD(P)H oxidases and maintaining photosynthetic electron transport (Cakmak 2005). In addition, enhanced K nutritional status induces a number of beneficial physiological effects. These include stimulation of root growth, increases of leaf area, chlorophyll content and the net assimilation rate (NAR). Plant water content is also closely regulated by the effects of K on closure and opening of stomata which maintains photosynthetic CO2 fixation. Additionally K reduces undesirable excess uptake of ions such as Na and Fe as well as benefiting N metabolism as for example by stabilizing nitrate reductase (NR) (Khan 1991; Marschner 1995; Elstner and Osswald 1994; Mengel and Kirkby 2001; Umar 2006). K nutrition has been shown to decrease the uptake of Cd as observed in wheat (Triticum aestivum L.) (Zhao et al. 2004). The present study investigates whether K nutrition may protect plants from Cd-toxicity-induced oxidative damage by reducing the Cd availability to the plant thereby depressing the contents of H2O2 and TBARS in the mustard leaves.

Materials and methods (see details in the online version):

- Plant material and treatments
- Growth parameters and net photosynthetic traits
- Estimation of glutathione, ascorbate and K contents
- Estimation of thiobarbituric acid reactive substances and H2O2
- Estimation of cadmium content
- Statistical analysis

Results

Plant growth parameters

All applications of Cd reduced plant dry mass and leaf area significantly (P ≤ 0.05) (Table 1). Application of 100 mg Cd/kg soil caused maximum reduction, compared with the control. Plant dry mass was reduced by 15.90%, 30.78% and 46.67%, and leaf area by 16.84%, 42.16% and 42.44% due to application of 25, 50 and 100 mg Cd/kg soil, respectively, in comparison with control. K application (60 mg/kg soil) alleviated Cd toxicity and lowered the reductions caused by Cd. K alleviation effect was more pronounced with the lowest level of Cd (25 mg/kg soil) followed by 50 and 100 mg Cd/kg soil. With the application of 60 mg K/kg soil, plant dry mass increased by 38.41%, 31.11% and 16.35%, compared to that at 25, 50 and 100 mg Cd/kg soil, respectively. K application increased the leaf area maximally (28.23%) at 25 mg and minimally (3.76%) at 100 mg/Cd kg soil.

Photosynthetic traits

Relative to the control, the chlorophyll content, net photosynthetic rate, stomatal conductance and concentration of internal CO2 decreased significantly at P ≤ 0.05 level as determined by the Duncan’s multiple range test.

![Fig. 1. Chlorophyll content, net photosynthetic rate, stomatal conductance and internal CO2 concentration in Brassica campestris L. leaves as influenced by Cd stress and K nutrition at 30 d after sowing. Values are means ± SE (n = 3). Data followed by the same letter are not significantly different at P≤0.05 level as determined by the Duncan’s multiple range test.](image)

Table 1: Plant dry mass and leaf area of Brassica campestris L. as influenced by Cd stress and K nutrition at 30 d after sowing. Values are means ± SE (n = 3). Data followed by the same letter are not significantly different at P≤0.05 level as determined by the Duncan’s multiple range test.
Research findings

soil (Fig. 1a-d). K supplementation to Cd-exposed plants improved the content of chlorophyll by 37.04%, 24.47% and 6.78% at 25, 50 and 100 mg Cd/kg soil, respectively (Fig. 1a). The net photosynthetic rate increased with K application by 21.20%, 6.19% and 5.04%, with 25, 50 and 100 mg Cd/kg soil, respectively (Fig. 1b), whereas stomatal conductance decreased by 17.50%, 47.50% and 72.50% with 25, 50 and 100 mg Cd/kg soil (without K), respectively. Data in Fig. 1c reveal that the stomatal conductance increased due to supply of K (60 mg/kg soil) to Cd-exposed mustard plants, the extent of increase varying with treatments. Stomatal conductance increased by 48.48%, 23.81% and 27.27% when 25, 50 and 100 mg Cd/kg soil was added (Fig. 1c). Concentration of internal CO₂ decreased maximally with 100 mg Cd/kg soil (43.79%) followed by 50 mg Cd/kg soil (31.81%) and 25 mg Cd/kg soil (6.37%). K supplementation to Cd-exposed plants improved the CO₂ level by 20.59%, 16.39% and 7.73% at 25, 50 and 100 mg Cd/kg soil, respectively (Fig. 1d).

TBARS and H₂O₂ contents

To evaluate the Cd-induced oxidative damage to membranes, contents of TBARS and H₂O₂ were determined. The presence of Cd in the soil caused a significant (P ≤ 0.05) increase in TBARS content in mustard leaves (Fig. 2a). The H₂O₂ content in mustard leaves with supply of Cd alone was also maximum (269%) at 100 mg, followed 110% at 50 mg and 38.04% at 25 mg Cd/kg soil. Application of K to Cd-exposed plants decreased the H₂O₂ content maximally (43.17%) at 25 mg, followed by 22.53% at 50 mg and 9.76% at 100 mg Cd/kg soil (Fig. 2b).

Cadmium content

Addition of Cd to the soil caused an increase in Cd content of mustard leaves, as expected (Fig. 2c). Plants grown in the soil without Cd also contained some Cd, although the contents were very low, resulting probably from soil contamination caused by agricultural chemicals. Significant differences in leaf Cd content (P ≤ 0.05) were found in plants grown with 100, 50 and 25 mg Cd/kg soil (without K). With application of K (60 mg/kg soil) to the soil, Cd content of leaf decreased significantly, indicating an antagonistic effect of K nutrition on Cd uptake by plants. The leaf Cd content decreased by 25.53%, 12.21% and 5.25% at 25, 50 and 100 mg Cd/kg soil, respectively (Fig. 2c).

Contents of ascorbate, glutathione and potassium

The content of ascorbate decreased by 14.74%, 37.89% and 63.63% at 25, 50 and 100 mg Cd/kg soil (without K), respectively. As shown in Table 2, the ascorbate content increased with addition of K (60 mg/kg soil) to the Cd-exposed plants, the increase being treatment dependent. The content of leaf ascorbate increased with K application by 33.33%, 24.58% and 8.45% on application of 25, 50 and 100 mg Cd/kg soil, respectively (Table 2). The influence of K and Cd treatments on glutathione content of leaves is shown in

| Table 2. Contents of AsA, GSH and K in Brassica campestris L. leaves as influenced by Cd stress and K nutrition at 30 d after sowing. Values are means ± SE (n = 3). Data followed by the same letter are not significantly different at P ≤ 0.05 level as determined by the Duncan’s multiple range test.

Research findings

Fig. 1c. It decreased significantly (P≤ 0.05) at 100 mg Cd (68.29%), 50 mg Cd (41.16%) and 25 mg Cd/kg soil (21.04%). Application of K (60 mg/kg soil) reduced the decline in glutathione content substantially; the effect being more pronounced with the lowest Cd treatment (25 mg Cd/kg soil). Thus, maximum content of glutathione occurred with 25 mg Cd (25.48%), followed by the value of 15.54% with 50 mg Cd and 8.65% with 100 mg Cd/kg soil when supplemented with 60 mg K/kg soil (Table 2). The content of potassium decreased by 5.80%, 14.36% and 21.82% at 25, 50 and 100 mg Cd/kg soil (without K), respectively. As shown in Table 2, potassium content increased with addition of K (60 mg/kg soil) to the Cd-exposed plants, the increase being treatment dependent. The content of leaf K increased with K application by 5.28%, 3.87% and 2.12% on application of 25, 50 and 100 mg Cd/kg soil, respectively (Table 2).

Discussion

Cadmium treatment causes oxidative stress in plants through increase in the production of H$_2$O$_2$ (Kuo and Kao 2004; Schutzendubel et al. 2001; Olmos et al. 2003) and induction of lipid peroxidation (Chien et al. 2002; Gallego et al. 1996a, b; Noctor and Foyer 1998). AsA contributes directly to ROS scavenging and by means of ascorbate peroxidase (APX). The decrease in AsA and GSH contents in mustard leaves treated with Cd suggests that AsA and GSH contents may be regulated by the synthesis and oxidation. GSH is the precursor of phytochelatins, cysteine-rich peptides synthesized via phytochelatin synthase (Cobbett and Goldsbrough 2002). GSH is severely depleted in response to Cd due to its increased consumption in phytochelatin production (Schutzendubel and Polle 2002).

The present results indicate that K nutrition decreased the Cd-induced decline in the AsA and GSH contents (Table 2). The capacity of K to scavenge H$_2$O$_2$ in mustard leaves was at a maximum with 60 mg K/kg soil plus Cd (Fig. 2b). In considering a possible mechanism for the depression of Cd-induced oxidative damage by K nutrition, it may be supposed that K might inhibit Cd uptake from the medium i.e. an antagonistic effect between Cd and K uptake (Zha et al. 2004). This is supported by our findings which have shown that the Cd content in mustard leaves treated with K$_60$ + Cd levels was lower than in those treated with Cd alone (Fig. 2c). Our findings suggest that increase in the K nutrient status of plants may prevent, though slightly (27%), the uptake of Cd. K$_60$ + Cd levels treatment inhibited, almost completely, the Cd-induced generation of H$_2$O$_2$ and lipid peroxidation (TBARS) in mustard leaves (Fig. 2a-b). It may thus be concluded that K nutrition by depressing Cd uptake is able to protect plants from Cd-induced oxidative burst thereby avoiding H$_2$O$_2$ and TBARS generation.

III Potassium improves grain filling - a short story in pictures and figures from India, Indonesia and China

Potassium improves grain filling of wheat

Results shown here are the average figures for 24 plants from five varieties and four replicates.

The yield of a grain crop depends on (a) the number of ears per unit area, (b) the number of ripe grains per ear, and (c) the weight of the grain (the so-called 1000 grain weight). Due to its influence on photosynthesis and assimilate transport, potassium is particularly effective in the improvement of grain number and (1,000) grain weight. This has been confirmed not only in pot experiments with wheat, as shown in the Fig. 1, but also in numerous field trials with this and other cereal crops, as demonstrated in the next photos and figures obtained from various experiments in which IPI is involved.

Fig. 1. Effect of exchangeable K in soil on yield and its components in wheat. Source: Slide #6; IPI slides on Potassium in plant production. This and other slides are available on the IPI website at http://www.ipipotash.org/publications/detail.php?id=73

Wheat in India

Plate 1 reveals a typical response of K application to wheat. The wheat crop was grown on a low K soil (30 mg/kg) and received 120 and 60 kg N & P₂O₅ respectively, with an additional 60 kg K₂O/ha to the K+ plot. As shown, grain filling is much improved with potassium application. Source: IPI-ICAR experiment, India. 2004.

Plate 1. Wheat grain in response to K application. Photo by S. Bansal, Potash Research Institute of India (PRII).
Research findings

Potassium increases grain filling in rice: an example from Indonesia.

Plate 2 shows a typical response of K application in rice, through better grain filling. The picture shows a panicle and the grain removed from it taken from a plot not fertilized with K (left) compared with that from a plot fertilized with K (right). Grains from the panicle were removed and categorized as i) unfilled, ii) partially filled and iii) fully filled. In both samples, the grains at the top are those unfilled, the grains in the middle are partially filled, and the grains on the bottom are filled. Clearly, the sample from –K has a much larger proportion of unfilled and partially filled grain.

*****

Potassium increases grain filling in maize: an example from Sichuan, China.

The effect of K fertilization on grain filling of maize is shown in Plate 3. The picture was taken at IPI-SFI Chengdu project in maize-sweet potato-winter wheat intensive cropping system. Both treatments received the recommended dose of 230 kg N/ha and 90 kg P₂O₅/ha. The +K plot received 175 kg K₂O/ha.

The results from this experiment demonstrate how the application of both potash and organic matter (OM) had a significant effect on grain weight during 1998 and 1999 (Fig. 2). Interestingly, application of OM had a positive effect on grain weight in both years, especially at K=0, suggesting that the potassium in the OM is important as a nutrient input, and has to be calculated accordingly.

Events

In March 2008:

The workshop was jointly organized by IPI, Bangladesh Rice Research Institute (BRRI) and Bangladesh Fertilizer Association (BFA).

Presentations are available on the IPI website and the “Special Issue 2008 (Vol. 4) of Bangladesh Journal of Agriculture and Environment” (see link provided on page 13 in publications).

In September 2008:

IPI is organizing a satellite event at the meeting of the Soil Science Society of China, 24-27 September 2008. This will be an opportunity to report and discuss recent research findings obtained from various IPI projects in China. For more details see IPI website.

In November 2008:

17th International Symposium of CIEC, 24-27 November 2008, Cairo, Egypt.

The International Scientific Centre for Fertilizers (CIEC) is organizing a symposium titled “Plant nutrient management under stress conditions”, hosted by the National Research Center (NRC), Egypt. For more details contact nrc-mic@link.net or oeabk@yahoo.com. Details also on IPI website.

In December 2008:

Second International Symposium on Papaya, 9-12 December 2008, Madurai, Tamil Nadu, India.

This symposium is being jointly organized by the International Society for Horticultural Science (ISHS), Leuven, Belgium in collaboration with Tamil Nadu Agricultural University, Coimbatore, India and other scientific organizations. The theme of the symposium is “Papaya for nutritional security”. For further details, please contact the organizing secretary, Dr. N. Kumar, Professor (Horticulture), Tamil Nadu Agricultural University, Coimbatore 641 003, India. E-mail: kumarhort@yahoo.com, Phone: +91 422-6611310/6611377, (R): +91 422-2436046; Fax: +91 422-6611399, Mobile: +91 936 312 1916. Web: www.ishs-papaya2008.com. Details also on IPI website.

In July 2009:

IPI-Corvinus University Budapest international symposium on “Nutrient management and nutrient demand of energy plants”, 6-9 July 2009, Budapest, Hungary.

The symposium will be jointly organized by IPI and Corvinus University Budapest. Venue: Mercure Budapest, Hungary. Topics will include quality requirements of crops for biofuels, new and traditional crops for biofuel, energy and CO₂ balance of crops grown for biofuels and optimal crop rotation and nutrient balance for bio fuel plants. The post-symposium tour will be to a biofuels plant and farmers growing energy crops. Registration fee will cover participation at all oral and poster presentations, welcome reception, lunch, morning and afternoon coffee break the during two symposium days, and symposium dinner. The post-symposium tour will be charged separately. For more details see IPI website or contact IPI Coordinator Dr. T. Popp.

The value of nutrients in straw (adapted from “Cereal Straw – Nutrient Content” by the PDA, March 2008).

Calculation of the content of P and K in straw of winter and spring cereal crops show a significant amount of available nutrients

**Bangladesh Journal of Agriculture and Environment, special edition.** Proceedings of the IPI-BRRI-BFA International Workshop on 'Balanced Fertilization for Increasing and Sustaining Crop Productivity', 30 March - 1 April 2008, Dhaka, Bangladesh. 190 p., edited by M.S. Islam. ISSN 1816-0808. Bangladesh Fertilizer Association (BFA). This international symposium was jointly organized by the International Potash Institute (IPI), Bangladesh Rice Research Institute (BRRI), and the Bangladesh Fertilizer Association (BFA).

The proceedings contain 13 papers covering issues of soil fertility, fertilization with potassium in rice-rice and rice-wheat cropping systems, site specific nutrient management (SSSNM), integrated nutrient management, fertilizer recommendation and policies in Bangladesh. Papers from India cover balanced fertilization in the horticultural sector and fertilizer-related policies.

To order a copy, contact the Assistant Editor, Bangladesh Journal of Agriculture and Environment (BJAE), Bangladesh Fertilizer Association, City Heart Building (10th Floor), Room #8, 67 Naya Paltan, Dhaka-1000, Bangladesh. **K in the literature**

http://www.fertiliser-society.org/Proceedings/UK/Prc615.HTM

Abstract:
The potassium (K) status of the soil has a considerable influence on crop uptake and response to nitrogen (N). Yield response to applied fertiliser N is decreased by low concentrations of exchangeable K in the soil. The basis of this interaction is explored using historical and current data from Rothamsted Research's experiments at Rothamsted, Saxmundham, Woburn and Broom's Barn on spring barley, winter wheat, potatoes, sugar beet, mangels and grass. It is argued that the agronomic responses derive from the physiologically interacting effects of N and K on tissue hydration and consequential osmotic adjustments in shoot tissues.

****

http://www.fertiliser-society.org/Proceedings/UK/Prc618.HTM

Abstract:
Potassium (K) is a key nutrient with widespread impact and functions within the complexity of grassland based livestock production. It has received relatively little research attention in recent years, but much is known about its behaviour, content and specific roles in each of the component parts of a livestock farm. Requirements for optimised supplies to forage crops are well known, as is K distribution and availability in soils. The interactions of K with other elements which are of importance to the nutritional well-being of livestock, especially lactating ruminants, have also been well described, and whilst the effects can be confounded by interactions with other factors, good advice is available to minimise risk. Nevertheless, it is timely to consider K in a more systematic way within the whole production cycle so that any potential imbalances in supply per se, or in relation to other nutritional requirements for optimised plant and animal performance, can be identified at an early stage. Knowledge of soil, field and farm K balances is one means of providing guidance on actions that may need to be taken from both tactical and strategic perspectives. Examples are provided of effects at various stages of the production cycle and of opportunities to improve balances.

http://www.fertiliser-society.org/Proceedings/UK/Prc618.HTM

Abstract:
The management of productive grass swards is primarily driven by the appropriate use of relatively large dressings of nitrogen, both from fertilisers and manures. The basis for current fertiliser recommendations was laid by a large number of experiments carried out in the UK between the 1940s and 1960s. These experiments are identified and their findings reported. Both costs and outputs must be assessed. Increasingly aspects relating to water quality and pollution hazards to the environment must be considered. High yields of conserved grass inevitably remove large quantities of potassium from the field when harvested. This potassium must be replaced if soil fertility is not to decline. The percentage of potassium in the herbage DM (especially late in the previous season) is a good indicator of the essential need for potassium fertilisation. Values below 2.0% potassium are indicative of serious depletion which should receive attention. UK experiments suggest that optimum yields can be obtained when herbage potassium concentration remains above 3.0% DM at the end of the previous season. The critically important relationship between the requirements for nitrogen and potassium by high-yielding grass swards is discussed and the extensive experimental evidence is reviewed.

http://www.fertiliser-society.org/Proceedings/UK/Prc619.HTM

Abstract:
Potassium and magnesium are essential nutrients for crop development. In the context of the Nitrates Directive and the Water Framework Directive, the focus is directed more towards nitrogen and phosphorus than towards potassium and magnesium, mainly because K and Mg have no real direct effects on the environment. In intensive agriculture the potassium and magnesium release from primary and secondary soil minerals is
K in the literature

too low to compensate for the offtake by the crop. Besides mineral fertilisers, large amounts of potassium and magnesium can be applied to the soil via animal manures and other organic by-products. Concentrations of K and Mg in all kinds of animal manures, composts, spent mushroom composts (champosts) and some secondary materials originating from processing agricultural products are given for various countries. From this overview a large variation in K and Mg content is obvious between countries but even more in a specific country. Causes for this high variability are diverse but to a large extent due to differences in dry matter content and the original contents in the primary products. It is generally accepted that the efficiency of K and Mg in animal manures and organic by-products is of the order of 80 to 100% compared to mineral K- and Mg-containing fertilisers. On the other hand, if applications of these organic materials are made during winter time, quite important losses, especially for potassium, can occur in light textured soils. Knowledge of at least the order of magnitude of the potassium and magnesium contents in these organic materials is necessary for the promotion of a sustainable agriculture.

http://www3.interscience.wiley.com/journal/117953388/abstract

Abstract:

Safflower may have a certain production potential under German conditions, particularly in organic farming where the putatively low nutrient requirement is highly welcomed. However, current knowledge regarding the nutrient requirements of safflower as compared to similar oil crops is limited. It was thus the aim of this study to determine the growth and yield response of safflower (Carthamus tinctorius L.) as compared to sunflower (Helianthus annuus L.) with respect to potassium (K) supply. Three safflower and two sunflower plants were cultivated in 5 L Mitscherlich pots. Both species responded strongly to increasing K supply with respect to plant growth and yield. Growth and yield of safflower increased up to 1 g K per pot, while the optimum for sunflower was 3.0 g K per pot. Safflower out-yielded sunflower at low K supply, while at high K level, the opposite was observed. Supply of K affected virtually all yield components in both species, though to different degree. The number of capitula in safflower was only slightly affected, and the number of achenes per capitulum was only reduced under severe K deficiency, while single-achene mass increased with increasing K supply. In sunflower, the number of achenes per capitulum strongly responded to the K supply, as did the single-achene mass. Oil yield in safflower was affected by K deficiency mainly due to reduced achene yield, not oil concentration. However, oil yield in sunflower was severely affected by low K supply due to both reduced achene yield and lowered oil concentration. Multiple-regression analyses indicate that in sunflower, the stem dry matter (DM) and the total amount of K accumulated in the aboveground biomass were most important, while in safflower the total amount of K and N accumulated had the highest impact. It is concluded that sunflower is more sensitive to inadequate K supply than safflower.

http://soil.scijournals.org/cgi/content/abstract/72/3/791

Abstract:

Ammonium acetate K does not adequately measure available K in the mineralogically diverse maize (Zea mays L.)-producing soils of Thailand. The objective of this study was to understand the causes of this problem and propose a solution using laboratory and greenhouse experiments to examine the release patterns and the availability of exchangeable and nonexchangeable K. Eight kaolinitic and smectitic soils were examined for the release of K in each soil fraction (sand, silt, and clay) using the Ca-resin successive extraction method. The data were fitted using parabolic diffusion, power function, and segmented straight line regression models. The power function and the segmented regression model fitted the data well. All soils were exhaustively cropped with maize in the greenhouse until the soils became K deficient. The results indicated that a segmented regression model described nonexchangeable K release to the Ca resin and to plants in a way that seemed to correspond with earlier predictions. According to the model, there were two fractions of nonexchangeable K, which were released at distinctly different rates. The greenhouse study yielded fast and slow K release rates from the nonexchangeable K pool of 0.45 to 0.85 and 0 mg kg-1 d-1, respectively, in kaolinitic soils and 1.60 to 1.98 and 0.27 to 0.52 mg kg-1 d-1, respectively, in smectitic soils. Our results suggested that NH4OAc-extractable K was suitable and sufficient to determine plant-available K in kaolinitic soils. In contrast, a successive Ca-resin extraction
Optimizing Crop Nutrition

K in the literature

characterization plus \( \text{NH}_2\text{OAc} \) extractable K was required to determine plant-available K in smectitic soils.
